Fresh shrimp for tempura can command upward of $10 a pound in Japan. An NMFS scientist reports on the culturing of this specialty.

Shrimp Culture in Japan

C.R. MOCK

One of the most valuable marine species in Japan is the “Kuruma-Ebi” (Penaeus japonicus) shrimp fishery, which commanded a price of 7 to 30 U.S. dollars per kilogram in 1971 at the Tokyo Central Fish Market. Although this price is high compared with U.S. prices, it is due to the fact that the Japanese people demand live shrimp for the preparation of a delicacy known as tempura.

Over the years much time has been spent developing methods of holding this species in ponds and rearing it to market size. Even though the Japanese have successfully reared shrimp through several generations, they explained that it was not economical to rear shrimp to sexual maturity because it was time-consuming and because the fecundity of the females was reduced. Therefore, gravid females are purchased directly from the commercial fishing fleets and then spawned.

Once the eggs have hatched, the water is fertilized to stimulate the growth of diatoms. Predetermined amounts of fertilizer and seawater are added each day to the tank until the larval shrimp have reached the last mysis stage. Brine shrimp nauplii (Artemia spp.) are fed from the last mysis stage through the fourth postlarval stage. The shrimp are then fed fresh meats of clams (Venerupis philippinarum) and mussels (Mytilus edulis), which are crushed and distributed throughout the ponds. Because it is too costly and time-consuming to separate the crushed shell from the meats, the shell eventually covers the pond bottom, resulting in a substrate that hamper the burrowing of the shrimps. Thus, ponds must be drained or dredged periodically to remove the shell debris.

Although larval rearing techniques are primarily the same today as they were 10 years ago, research in shrimp culture has been expanded because of three important factors: (1) the rising demand and costs for fresh food items to be fed to the shrimp; (2) the rising wages of employees; and (3) disease problems encountered.

Of particular interest is the use of a by-product of soy sauce production, a cake which is ground into powder to fertilize the water. Not only does it stimulate the growth of diatoms, but the larval shrimp also eat it. As the shrimp grow in size, this powder is either extruded or press into a size suitable for

1 Editor's note: Tempura is a method of cooking. Shrimp, other seafoods, chicken, fresh vegetables are dipped in batter and deep-fried. Recipes for the batter vary and are often a closely-guarded professional secret. Usually, foods cooked this way are served with a special sauce. It is popularly held that the technique was introduced into Japan by the Portuguese centuries ago. Tempura restaurants are a frequent and delightful feature of the Japanese scene.

eating. At the Kagoshima Prefecture Fisheries Experimental Station, the Director, Dr. K. Shigeno, remarked that although the shrimp ate this artificial food and grew to market size, the consumer was not satisfied with the quality or color of the prawns. He felt that the problem was primarily a vitamin deficiency. Artificial foods with a variety of additives are being tested at Dr. Shigeno's laboratory.

Research is also being directed toward rearing prawns to market size in a closed system. A 1,000-cubic meter cement tank (23 m in diameter and 3 m deep) has been built at the Tarumizu Kagoshima Prefecture Fish Experiment Station. The water temperature can be controlled, and a false bottom with airlift pipes has been installed as an in-bottom filter. Twenty-day-old postlarval shrimp have been stocked in this tank and reared to market size with good results. However, during two recent experiments a number of problems occurred, resulting in poor production.

Circulation of the water mass within a rearing system was emphasized for either fish or shrimp culture. At Tarumizu Kagoshima Prefecture Fish Experimental Station the flow was maintained with water jets, while a large mechanical stirrer was being tested at Setonai-ka Saibai Gyogyo Center, Tamano Jigyogojo.

At the Nansei Regional Fisheries Research Laboratory, Dr. H. Kurata spoke about the natural waves of *Penaeus japonicus* postlarvae that enter the estuaries. Monitoring of these waves now indicates that recruitment is presently less than in previous years. The total tonnage landed by the commercial shrimp fleet is also down. Therefore, the concept of seeding the system with $1.2 \times 10^8$ 20-day-old postlarval shrimp is being tested to see if the system is still a suitable environment, if production of shrimp can be stimulated, and if new areas can be used. Some shrimp are released directly into the nursery grounds, while others are placed in a pen (30 x 10 x 10 m) for 2 to 4 weeks to acclimate them to estuarine waters.

Dr. M. Fujiya, also of the Nansei Laboratory, began physiological studies to measure the "quality" of shrimp larvæ reared in different ways, by observing their reaction to anesthetics. His approach is to insert electrodes into the
Floating raft with electrical agitator used to maintain circulation and desired oxygen levels in ponds.

brain of the shrimp and record their brain waves on an oscilloscope.

Dr. H. Hirata, at Kagoshima University, has begun work on the production of single-species mass cultures of diatoms and their preservation. At present, diatoms are concentrated and later frozen at 0°C. They can be held successfully for periods of 30 days or less. Various other techniques are now being tested.

At the University of Tokyo, School of Fisheries, Dr. Ogoaowara and Dr. T. Sano discussed the culture of freshwater shrimp of the species *Macrobrachium*. Eleven different species were being studied. To rear the larval stages, they indicated that a medium of 50 percent fresh water and 50 percent seawater was necessary. A diet of *Artemia*, reared on a freshwater culture of *Chlorella*, is fed during the larval stages along with ground clam (*Tapes* sp.) meat. When the shrimp are older, pieces of chicken egg shells are added to supplement the calcium in their diets.

Juveniles of *Macrobrachium rosenbergi* have been reared on commercial trout pellets to market size in 6 months at the Izu Branch Laboratory. Although results have been satisfactory, production costs were not made available.
